in order to identify how the environmental factors contributed to the formation of each cluster we conducted a canonical correspondence analysis (cca). the cca is a multivariate statistical technique that uses the principle of correspondence between the data and the variables to determine the percentage of total variability in the data [71], [72] and to determine the main environmental factor that contributed to the formation of each cluster [73]. this analysis was conducted in the canoco 4.5 software [74] and showed that the variable with the highest contributions to the formation of each cluster was the soil texture. this was also related to the other variables [74] since the axis 1 of the cca explained 71% of the total variability. the information obtained from the cca is extremely useful for the development of future studies on the environmental factors that may influence the soil biota, since many studies on this topic are limited to one or two parameters. the second axis ([74]) explained 28% of the variability and was related to the variables ph and soil-water content. in this way, we identified the parameters that most influenced the distribution of the species within the clusters. multivariate analyses were performed in canoco to quantify the influence of the studied environmental factors on the structure of the soil nematode community. these are structure index (si), which is a measure of trophic linkage in soil food webs and indicates greater trophic links. higher si value indicates a food web that is more structured or stable, with more persisters (k-strategist) genera present (wang et al, 2006 ; briar et al, 2007). significant sampling sites and depths effects on si were found in the stable sand dune (zhang et al, 2010), but only sampling sites effect on si was observed in the present study. in conclusion, total number of soil free living nematodes, trophic groups and ecological indices used were a good tool for explaining soil habitat environment differences. soil free-living nematodes inhabited mostly the upper soil layers (0-20 cm) and nematode abundance was gradually decreasing trend with soil depths increasing in the playa and loessial plain area during the dry and wet seasons. sampling sites and depths significantly effected on nematode abundance and trophic groups, however, only sampling sites significantly effected on nematode ecological indexes. moreover, each soil layers had a little nematode abundance and community diversity in a playa area in contrast to loessial plain area during the dry and wet seasons. 5ec8ef588b
